ABSTRACT

Field experiments were conducted from July to November, during 2011 and 2012 cropping seasons at the Research Farm, University of Agriculture, Makurdi, Nigeria, to evaluate soybean-maize intercropping on yield and system productivity. Sole soybean, sole maize and the intercrop of soybean and maize constituted the treatments, which were laid out in a randomized complete block design with four replications. Results of study showed that intercropping soybean with maize significantly (P≤0.05) reduced soybean yield by 43.8 % and 55.6 % respectively, in 2011 and 2012. However, maize yield was not significantly (P≤0.05) affected when intercropped with soybean. Total intercrop yield was greater than the sole crop yields. Intercropping soybean and maize gave land equivalent ratio (LER) values of 1.40 and 1.29 respectively, in years 2011 and 2012, indicating that higher productivity per unit area was achieved by growing the two crops together than by growing them separately. With these LER values, 28.6 % and 22.5% of lands were saved respectively, in 2011 and 2012, which could be used for other agricultural purposes. In addition, land equivalent coefficient values exceeded 0.25, indicating yield advantage of the intercropping system. Competitive pressure of component crops was low, indicating that both crops are complementary and suitable in mixture.
1. Introduction

Soybean (*Glycine max* L. Merril) belongs to the legume family and is a native to East Asia (Dugje et al., 2009). It grows on a variety of soil and a wide range of climates (Ijoyah and Fanen, 2012). Soybean is an important crop in Nigeria. The country is the largest producer in West and Central Africa (Root et al., 1987). It has a high protein content of 40% by weight, 32% carbohydrate, 20% fat, 5% minerals and 3% fibre and other trace substances. It is used as sources of protein in human food and animal feed. It is also used in industries as a source of edible oil and the by-product of the oil extraction is the soybean cake used as animal feed (Atungu and Afolabi, 2001).

Maize (*Zea mays* L.) is an annual cereal plant of the gramineae family and native of Mexico (Hugar and Palled, 2008). Maize is Nigeria’s third most important cereal crop following sorghum and millet (Uzozie, 2001). It is grown for its grain which contains 65% carbohydrate, 10-12% protein and 4-8% fat (Iken and Amusa, 2004). The crop also contains the vitamins A, B, C and E, including mineral salts and essential trace elements such as carotene, thiamine, ascorbic acid and tocopherol (Groote, 2002). Maize is used mainly for human food and livestock feed, while in the industry, it is used in the production of starch, oil and alcohol (Kling and Edmeades, 1997).

Since the introduction of soybean to farmers in Makurdi, a location in Central Nigeria, various attempts have been made to include it in various crop types like tubers and cereals, however, ‘there is a dearth of scientific information on the performance of soybean under intercropping with cereals, particularly maize. This study was therefore designed to augment the currently available information.

2. Materials and methods

2.1. Site description and variety of crops

The experiments were conducted from July to November, 2011 and 2012 cropping seasons at the Research Farm of the University of Agriculture, Makurdi, Nigeria, to evaluate soybean-maize intercropping on yield and system productivity. The study location (7° 48'N, 8° 39'E) and at an altitude of 228 m above sea level, falls within the Southern Guinea savannah agroecological zone of Nigeria. The variety of soybean used was ‘TGX 1448-2E’ (medium maturing variety), while that of maize was ‘Downy mildew streak resistance-yellow’ (DMSR-Y). The varieties of crops are popularly grown by farmers within the locality.

2.2. Experimental area, design, treatments and planting

The experimental area (135.0 m²) which consisted of sandy-loam soil was ploughed, harrowed, ridged and divided into 12 plots. Each plot had an area of 9.0 m². Each plot consisted of three ridges in which 10 maize stands per ridge were sown at a spacing of 1 m x 30 cm, giving a total plant population of 30 maize plants per plot (33,333 maize plants per hectare equivalent). Soybean was spaced at an intra-row spacing of 5 cm to give a plant population of 180 plants per plot (200,000 plants per hectare equivalent). The trial area consisted of three treatments (Sole soybean, sole maize and the intercrop of soybean and maize), replicated four times in a randomized complete block design. Sole soybean and sole maize were respectively sown at their recommended intra-row spacing of 5 cm and 30 cm (Dugje et al., 2009; Ijoyah and Dzer, 2012). In soles and in intercrop, maize and soybean were sown at a depth of 2-3 cm.

2.3. Cultural practices

Mixed fertilizer NPK 15-15-15 was applied to sole maize at the rate of 200 kg ha⁻¹ while 100 kg ha⁻¹ of single superphosphate was applied to sole soybean and for soybean-maize mixture, 100 kg N ha⁻¹, 100 kg P ha⁻¹ and 100 kg K ha⁻¹ was applied (Enwezor et al., 1989). Weeding was done as the need arose.

Soybean was harvested when the pods have turned brown and seeds are at the hard-dough stage with moisture content between 14 and 16% (Dugje et al., 2009).

Maize was harvested at 12 weeks after planting (WAP) when the leaves turned yellowish and fallen off which were signs of senescence and cob maturity (Ijoyah and Jimba, 2012).
2.4. Data collection

Data taken on soybean include days to 50 % flowering, plant height (cm) at 8 weeks after planting (WAP), number of branches per plant, number of leaves per plant at 8 WAP, number of pods per plant, number of nodules per plant (determined by counting), nodule dry weight per plant, and seed yield (t ha$^{-1}$).

Data taken for maize include maize plant height at 50 % flowering (measured as the distance in cm from the soil surface to the collar of the top most leaf), days to 50 % flowering, number of cobs per plant, cob length (cm), cob diameter (the diameters at the head, centre and tail ends of the cobs were measured in cm and averaged) and cob weight (g). The cobs were later shelled manually and the total grains for each plot weighed to obtain the yield (t ha$^{-1}$).

2.5. Statistical analysis

All data were statistically treated using the Analysis of variance (ANOVA) for randomized complete block design and the Least Significant Difference (LSD) was used for mean separation (P≤0.05) following the procedure of Steel and Torrie (1980). The land equivalent ratio (LER) was determined as described by Willey (1985) using the formula:

$$\text{LER} = \frac{\text{Intercrop yield of crop A} + \text{Intercrop yield of crop B}}{\text{Sole crop yield of A}}$$

The land equivalent coefficient (LEC) as described by Adetiloye et al., (1983) was determined using the formula:

$$\text{LEC} = \frac{\text{La} \times \text{Lb}}{\text{La} + \text{Lb}}$$

where La: LER of main crop; Lb: LER of intercrop.

The competitive ratio (CR) as described by Willey and Rao (1980) was determined using the formula: CR = \(\frac{Lm}{Ls}\), where Lm: Partial LER for maize; Ls: Partial LER for soybean.

The percentage (%) land saved as described by Willey (1985) using the formula:

$$\% \text{ Land saved} = 100 - \frac{1}{\text{LER}} \times 100.$$ 

These calculations were used to assess the advantage of the intercropping system.

3. Results and discussion

3.1 Soybean yield

Yield of soybean as sole and in intercrop with maize at Makurdi, Nigeria in 2011 and 2012 cropping seasons is given in Table 1. Although, days to 50 % flowering for soybean was not significantly (P≤0.05) affected when intercropped with maize, however, intercropping took longer days to attain 50 % flowering compared to that recorded for soybean planted as a sole crop. The intense overcrowding of the intercrops could have prompted competitive demands on available nutrients and moisture, thus prolonging days to attain 50 % flowering (Ijoyah and Fanen, 2012).

Intercropping produced taller soybean plants than that obtained from monocropped soybean (Table 1). The competition for light from the greater population of plants in intercropping might have induced taller soybean plants.

Greater number of branches and leaves per plant were produced from monocropped soybean compared to those from intercropped soybean. This view agreed with Silwana and Lucas (2002) who reported that intercropping reduced vegetative growth of component crops.

The number of pods per plant was significantly (P≤0.05) greater for soybean planted as a sole crop compared to when sown in intercrop with maize (Table 1). The greater number of pods produced from monocropped soybean could have been influenced by its greater number of branches and leaves. This view supports Ijoyah et al., (2010), who reported that number of okra pods would depend on the intensity of plant growth. The number of pods produced from monocropped soybean was significantly (P≤0.05) greater by 42.3 % and 38.6 % respectively, in years 2011 and 2012 compared to that obtained from intercropped soybean.

Intercropping significantly (P≤0.05) reduced number of nodules per plant, nodule dry weight and seed yield compared to those produced from soybean planted as a sole crop (Table 1). Shading by taller maize plants could have contributed in the reduction of soybean yield. Higher yield in sole cropping over intercropping had also been reported by Olufajo (1992) and Muneer et al., (2004). Intercropping significantly (P≤0.05) reduced soybean yield by 43.8 % and 55.6 % respectively, in years 2011 and 2012.
3.2. Yield of maize

Yield of maize as sole and in intercrop with soybean at Makurdi, Nigeria in years 2011 and 2012 cropping seasons is given in Table 2.

Intercropping prolonged days to 50% flowering for maize. Competition for growth resources such as soil nutrients and moisture could have been responsible.

Intercropping did not significantly (P≤0.05) affect maize plant height at 50% flowering, number of cobs per plant, cob length, cob diameter, cob weight and grain yield (t ha⁻¹). The yield obtained from monocropped maize was however greater than that produced from intercropped maize (Table 2). This could be due to the greater number of cobs and cob weight obtained. The yield produced from monocropped maize was greater by 16.3% and 15.0% respectively, in years 2011 and 2012 compared to that obtained from intercropped maize.

3.3. System productivity

The total intercrop yield was greater than the component crop yields (Table 3). Intercropping soybean and maize gave land equivalent ratio (LER) values of 1.40 and 1.29 respectively, in years 2011 and 2012, indicating that higher productivity per unit area was achieved by growing the two crops together than by growing them separately (Table 3). With these LER values, 28.6% and 22.5% of lands were saved respectively, in 2011 and 2012, which could be used for other agricultural purposes. In addition, land equivalent coefficient (LEC) values for years 2011 and 2012 exceeded 0.25, indicating yield advantage of the system. Maize was about three-fifth (3/5) as competitive as soybean. The competitive pressure of component crops was low, thus, indicating that both crops were found complementary and suitable in mixture.

4. Conclusion

From the results obtained, it can be concluded that it is advantageous intercropping soybean and maize. This is associated with a greater total intercrop yield, higher land equivalent ratios greater than 1.0, indicating greater productivity per unit area and greater percentage of land saved, which could be used for other agricultural purposes. In addition, land equivalent coefficient values exceeded 0.25, indicating yield advantage of the intercropping system. Competitive pressures were low, signifying that the crops were found to be complementary and suitable in mixture. It is, however, recommended that further investigation be evaluated across different locations within the Southern Guinea savanna agroecological zone of Nigeria.
